ABSOLUTE MAXIMUM RATINGS⁽¹⁾

Supply Voltage+7V
Signal Input Terminals:	
Voltage ⁽²⁾ –0.5V to $V_{DD} + 0.5V$
Differential Amplifier ⁽³⁾ –10V to +10V
Current at IS1 and IS2 $\pm 75mA$
Current (pins other than IS1 and IS2) ⁽²⁾ $\pm 25mA$
I_{COMP} Short Circuit ⁽⁴⁾ +250mA
Operating Junction Temperature –50°C to +150°C
Storage Temperature –55°C to +150°C
ESD Rating:	
Human Body Model (HBM)	
Pins IA_{IN1} and IA_{IN2} Only 1kV
All Other Pins 4kV

- (1) Stresses above these ratings may cause permanent damage. Exposure to absolute maximum conditions for extended periods may degrade device reliability. These are stress ratings only, and functional operation of the device at these or any other conditions beyond those specified is not supported.
- (2) Input terminals are diode-clamped to the power-supply rails. Input signals that can swing more than 0.5V beyond the supply rails must be current limited, except for the differential amplifier input pins.
- (3) These inputs are not internally protected against over voltage. The differential amplifier input pins must be limited to 5mA, max or $\pm 10V$, max.
- (4) Power-limited; observe maximum junction temperature.

This integrated circuit can be damaged by ESD. Texas Instruments recommends that all integrated circuits be handled with appropriate precautions. Failure to observe proper handling and installation procedures can cause damage.

ESD damage can range from subtle performance degradation to complete device failure. Precision integrated circuits may be more susceptible to damage because very small parametric changes could cause the device not to meet its published specifications.

FUNCTIONAL PRINCIPLE OF CLOSED-LOOP CURRENT SENSORS WITH MAGNETIC PROBE USING THE DRV401

Closed-loop current sensors measure current over wide frequency ranges, including dc. These types of devices offer a contact-free method as well as excellent galvanic isolation performance combined with high resolution, accuracy, and reliability.

At dc and in low-frequency ranges, the magnetic field induced from the current in the primary winding is compensated by a current flowing through a compensation winding. A magnetic field probe, located in the magnetic core loop, detects the magnetic flux. This

probe delivers the signal to the amplifier that drives the current through the compensation coil, bringing the magnetic flux back to zero. This compensation current is proportional to the primary current, relative to the winding ratio.

In higher frequency ranges, the compensation winding acts as the secondary winding in the current transformer, while the H-bridge compensation driver is rolled off and provides low output impedance.

A difference amplifier senses the voltage across a small shunt resistor that is connected to the compensation loop. This difference amplifier generates the output voltage that is referenced to REF_{IN} and is proportional to the primary current. Figure 1 shows the DRV401 used as a compensation current sensor.

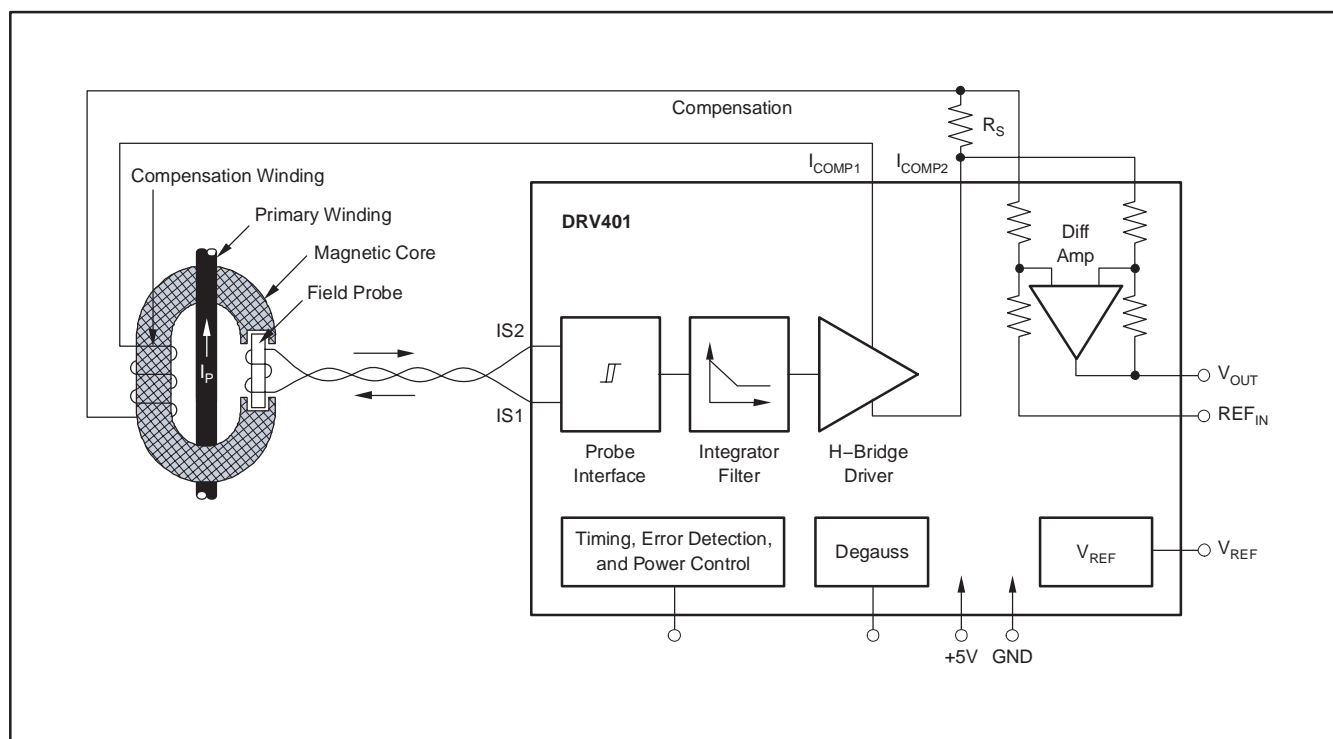

Figure 1. Principle of Compensation Current Sensor with the DRV401

FUNCTIONAL DESCRIPTION

The DRV401 operates from a single +5V supply. It is a complete sensor signal conditioning circuit that directly connects to the current sensor, providing all necessary functions for the sensor operation. The DRV401 provides magnetic field probe excitation, signal conditioning, and compensation coil driver amplification. In addition, it detects error conditions and handles overload situations. A precise differential amplifier allows translation of the compensation current into an output voltage using a small shunt resistor. A buffered voltage reference can be used for comparator, analog-to-digital converter (ADC), or bipolar zero reference voltages.

Dynamic error correction ensures high dc precision over temperature and long-term accuracy. The DRV401 uses analog signal conditioning; the internal loop filter and integrator are switched capacitor-based circuits. Therefore, the DRV401 allows combination with high-precision sensors for exceptional accuracy and resolution. The typical characteristic curve, *DRV401 and Sensor Linearity*, shows an example of the linearity and temperature stability achieved by the device.

A demagnetization cycle can be initiated on demand or on power-up. This cycle reduces offset and restores high performance after a strong overload condition. An internal clock and counter logic generate the degauss function. The same clock controls power-up, overload detection and recovery, error, and time-out conditions.

The DRV401 is built on a highly reliable CMOS process. Unique protection cells at critical connections enable the design to handle inductive energy.

MAGNETIC PROBE (SENSOR) INTERFACE

The magnetic field probe consists of an inductor wound on a soft magnetic core. The probe is connected between pins IS1 and IS2 of the probe driver that applies approximately +5V (the supply voltage) through resistors across the probe coil (see Figure 2a).

The probe core reaches saturation at a current of typically 28mA (see Figure 2a). The comparator is connected to V_{REF} by approximately 0.5V. A current comparator detects the saturation and inverts the excitation voltage polarity, causing the probe circuit to oscillate in a frequency range of 250kHz to 550kHz. The oscillating frequency is a function of the magnetic properties of the probe core and its coil.

The current rise rate is a function of the coil inductance: $dl = L \times V \times dT$. However, the inductance of the field probe is low while its core material is in saturation (the horizontal part of the hysteresis curve) and is high at the vertical part of the hysteresis curve. The resulting inductance and the series resistance determine the output voltage and current versus time performance characteristic.

Without external magnetic influence, the duty cycle is exactly 50% because of the inherent symmetry of the magnetic hysteresis; the probe inductor is driven from $-B$ saturation through the high inductance range to $+B$ saturation and back again in a time-symmetric manner (see Figure 2b).

If the core material is magnetized in one direction, a long and a short charge time result because the probe current through the inductors generates a field that either subtracts or adds to the flux in the probe core, either driving the probe core out of saturation or further into saturation (see Figure 2c). The current into the probe is limited by the voltage drops across the probe driver resistors.

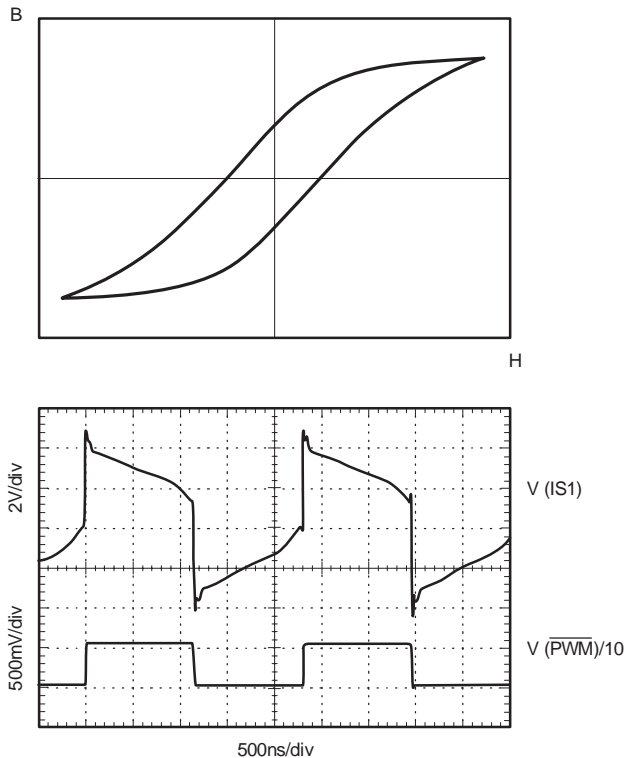

The DRV401 continuously monitors the logic magnetic flux polarity state. In the case of distortion noise and excessive overload that could fully saturate the probe, the overload control circuit recovers the probe loop. During an overload condition, the probe oscillation frequency increases to approximately 1.6MHz until limited by the internal timing control.

In an overload condition, the compensation current (I_{COMP}) driver cannot deliver enough current into the sensor secondary winding, and the magnetic flux in the sensor main core becomes uncompensated.

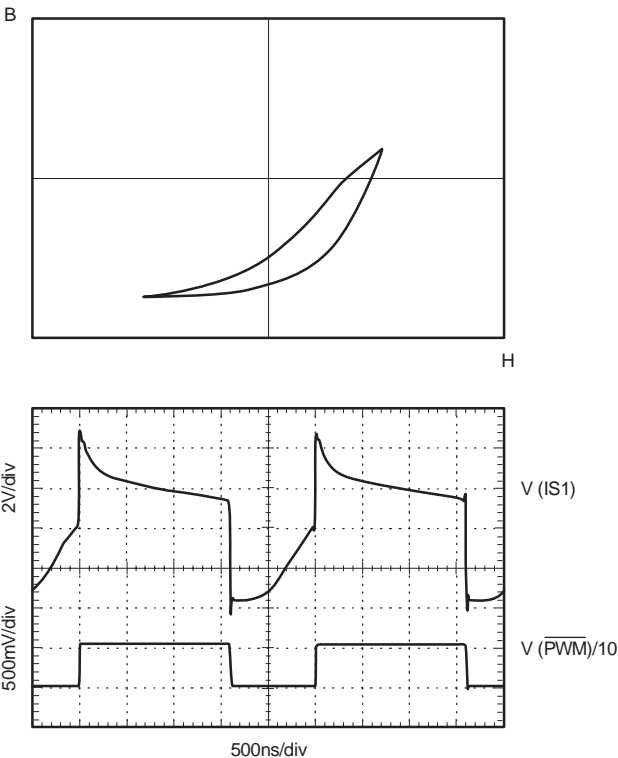

NOTE: MOS components function as switches only.

a) Simplified probe interface circuit.
The probe is connected between S1 and S2.

b) Without an external magnetic field, the hysteresis curve is symmetrical and the probe loop generates 50% duty cycle.

c) An external magnetic flux (H) generated from the primary current (I_{PRIM}) shifts the hysteresis curve of the magnetic field probe in the H-axis and the probe loop generates a nonsymmetrical duty cycle.

Figure 2. Magnetic Probe, Hysteresis, and Duty Cycle

The transition from normal operation to overload happens relatively slowly, because the inherent sensor transformer characteristics induce the initial primary current step, as shown in Figure 3. As the transformer-induced secondary current starts to decay, the compensation feedback driver increases its output voltage to maintain the sensor core flux compensation at zero.

When the system compensation loop reaches its driving limit, the rising magnetic flux causes one of the probe PWM half-periods to become shorter. The minimum half-period of the probe oscillation is limited by the internal timing to 280ns, based on the properties of the VAC magnetic sensors. After three consecutive cycles of the same half-period being shorter than 280ns, the DRV401 goes into overload-latch mode. The device stores the I_{COMP} driver output signal polarity and continues producing the skewed-duty cycle PWM signal. This action prevents the loss of compensation signal polarity information during very strong overloads. In this case, both PWM half-periods are short and approximately equal, because the field probe stays completely in one of the saturated regions.

The overload-latch condition is removed after the primary current goes low enough for the I_{COMP} driver to compensate, and both half-periods of the probe driver oscillation become longer than 280ns (the field probe comes out of the saturated region).

Peak voltages and currents can be generated during normal operations as well as overload conditions. Therefore, both probe connection pins are internally

protected against coupled energy from the magnetic core. Wiring between probe and IC inputs should be short and guarded against interference; see *Layout Considerations*. For reliable operation, error detection circuits monitor the probe operation:

1. If the probe driver comparator (CMP) output stays low longer than 32µs, the ERROR flag asserts active, and the compensation current (I_{COMP}) is set to zero.
2. If the probe driver period is less than 275ns on three consecutive pulses, the ERROR flag asserts active.

See the *Error Conditions* section for more details.

PWM PROCESSING

The outputs PWM and \overline{PWM} represent the probe output signal as a differential PWM signal. It can drive external circuitry or be used for synchronous ripple reduction. The PWM signal from the probe excitation and sense stage is internally connected to a high-performance, switched-capacitor integrator followed by an integrating-differentiating filter. This filter converts the PWM signal into a filtered delta signal and prepares it for driving the analog compensation coil driver. The gain roll-off frequency of the filter stage is set to provide high dc gain and loop stability. If additional gain is added from external circuitry, the internal gain can be reduced by 8dB, asserting the GAIN pin high (see the *External Compensation Coil Driver* section).

A current pulse of 0A to 18A (Ch 1) generates the two I_{COMP} signals (Ch 3 and Ch 4). Ch 2 shows the resulting output signal, V_{OUT} . This test uses the M4645-X030 sensor, no bandwidth limitation, but a 20-sample average.

Figure 3. Primary Current Step Response

COMPENSATION DRIVER

The compensation coil driver provides the driving current for the compensation coil. A fully differential driver stage offers high signal voltages to overcome the wire resistance of the coil with only +5V supply. The compensation coil is connected between I_{COMP1} and I_{COMP2} , both generating an analog voltage across the coil (see Figure 3) that turns into current from the wire resistance (and eventually from the inductance). The compensation current represents the primary current transformed by the turns ratio. A shunt resistor is connected in this loop and the high-precision difference amplifier translates the voltage from this shunt to an output voltage.

Both compensation driver outputs provide low impedance over a wide frequency range to insure smooth transitions between the closed-loop compensation frequency range and the high-frequency range, where the primary winding directly couples the primary current into the compensation coil at a rate set by the winding ratio.

The two compensation driver outputs are designed with protection circuitry to handle inductive energy. However, additional external protection diodes might be necessary for high current sensors.

For reliable operation, a wire break in the compensation circuit can be detected. If the feedback loop is broken, the integrating filter drives the outputs I_{COMP1} and I_{COMP2} to the opposite rails. With one of these pins coming within 300mV to ground, a comparator tests for a minimum current flowing between I_{COMP1} and I_{COMP2} . If this current stays below the threshold current level for at least 100μs, the ERROR pin is asserted active (low). The threshold current level for this test is less than 57mA at 25°C and 65mA at -40°C, if the I_{COMP} pins are fully railed (see the Typical Characteristics).

For sensors with high winding resistance (compensation coil resistance + R_{SHUNT}) or connected to an external compensation driver, this function should be disabled by pulling the CCdiag pin low.

$$R_{MAX} = \frac{V_{OUT}}{65mA} \quad (1)$$

Where:

V_{OUT} equals the peak voltage between I_{COMP1} and I_{COMP2} at a 65mA drive current.

R_{MAX} equals the sum of the coil and the shunt resistance.

EXTERNAL COMPENSATION COIL DRIVER

An external driver for the compensation coil can be connected to the I_{COMP1} and I_{COMP2} outputs. To prevent a wire break indication, CCdiag has to be asserted low.

An external driver can provide both a higher drive voltage and more drive current. It also moves the power dissipation to the external transistors, thereby allowing a higher winding resistance in the compensation coil and more current. Figure 4 shows a block diagram of an external compensation coil driver. To drive the buffer, either one or both I_{COMP} outputs can be used. Note, however, that the additional voltage gain could cause instability of the loop. Therefore, the internal gain can be reduced by approximately 8dB by asserting the GAIN pin high. R_{SHUNT} is connected to GND to allow for a single-ended external compensation driver. The differential amplifier can continue to sense the voltage, and used for the gain and over-range comparator or ERROR flag.

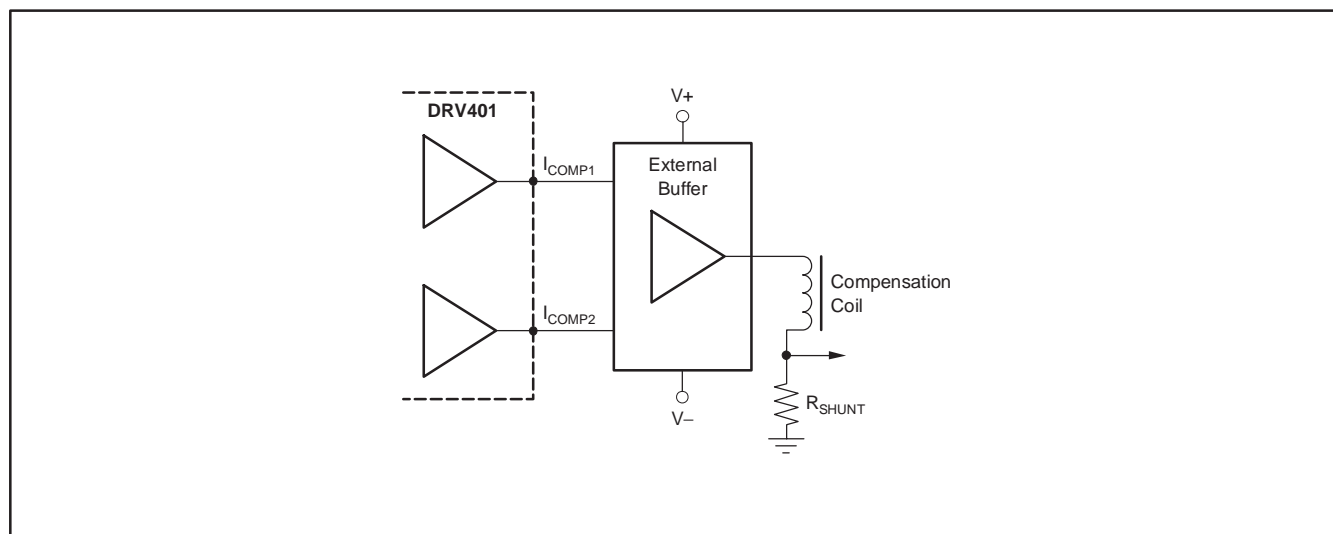

Figure 4. DRV401 with External Compensation Coil Driver and R_{SHUNT} Connected to GND

SHUNT SENSE AMPLIFIER

The differential (H-bridge) driver arrangement for the compensation coil requires a differential sense amplifier for the shunt voltage. This differential amplifier offers wide bandwidth and a high slew rate for fast current sensors. Excellent dc stability and accuracy result from an auto-zero technique. The voltage gain is 4V/V, set by precisely matched and stable internal SiCr resistors.

Both inputs of the differential amplifier are normally connected to the current shunt resistor. This resistor adds to the internal (10kΩ) resistor, slightly reducing the gain in this leg. For best common-mode rejection (CMR), a dummy shunt resistor (R_5) is placed in series with the REF_{IN} pin to restore matching of both resistor dividers, as shown in Figure 5a.

For gains of 4V/V:

$$4 = \frac{R_2}{R_1} = \frac{R_4 + R_5}{R_{SHUNT} + R_3} \quad (2)$$

With $R_2/R_1 = R_4/R_3 = 4$; $R_5 = R_{SHUNT} \times 4$

Typically, the gain error resulting from the resistance of R_{SHUNT} is negligible; for 70dB of common-mode rejection, however, the match of both divider ratios needs to be better than 1/3000.

The amplifier output can drive close to the supply rails, and is designed to drive the input of a SAR-type ADC; adding an RC low-pass filter stage between the DRV401 and the ADC is recommended. This filter not only limits the signal bandwidth but also decouples the high-frequency component of the converter input sampling noise from the amplifier output. For R_F and C_F values, refer to the specific converter recommendations in the specific product data sheet. Empirical evaluation may be necessary to obtain optimum results.

The output can drive 100pF directly and shows 50% overshoot with approximately 1nF capacitance. Adding R_F allows much larger capacitive loads, as shown in Figure 5b and Figure 5c. Note that with R_F of only 20Ω, the load capacitor should be either smaller than 1nF or larger than 33nF to avoid overshoot; with R_F of 50Ω this transient area is avoided.

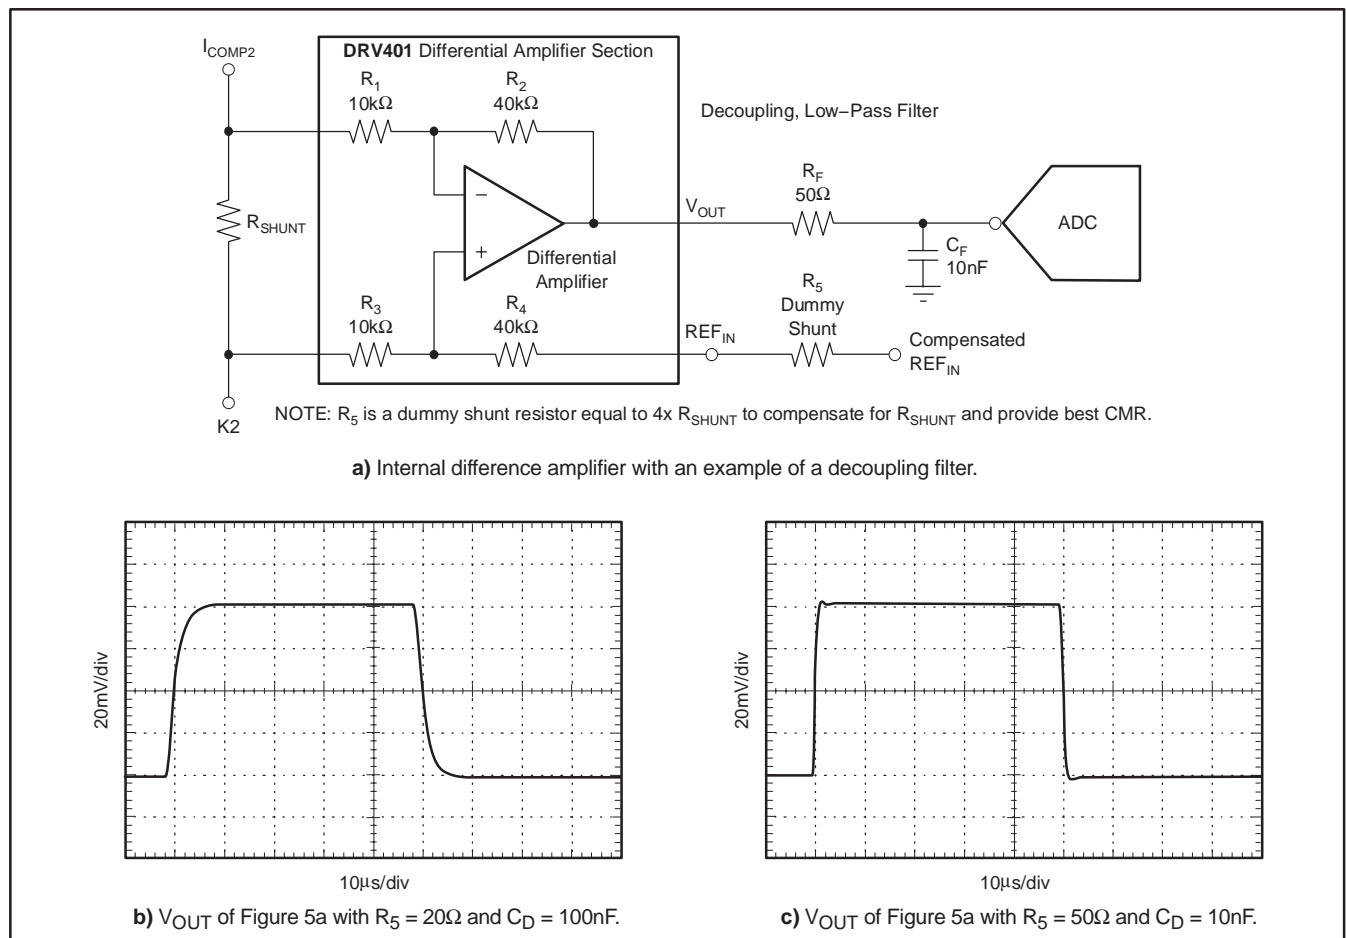

Figure 5. Internal Difference Amplifier with Example of a Decoupling Filter

The reference input (REF_{IN}) is the reference node for the exact output signal (V_{OUT}). Connecting REF_{IN} to the reference output (REF_{OUT}) results in a live zero reference voltage of 2.5V. Using the same reference for REF_{IN} and the ADC avoids mismatch errors that exist between two reference sources.

OVER-RANGE COMPARATOR

High peak current can overload the differential amplifier connected to the shunt. The OVER-RANGE pin, an open-drain output, indicates an over-voltage condition for the differential amplifier by pulling low. The output of this flag is suppressed for 3 μ s, preventing unwanted triggering from transients and noise. This pin returns to high as soon as the overload condition is removed (external pull-up required to return the pin high).

This ERROR flag not only provides a warning about a signal clipping condition, but is also a window comparator output for actively shutting off circuits in the system. The value of the shunt resistor defines the operating window for the current. It sets the ratio between the nominal signal and the trip level of the Over-Range flag. The trip current of this window comparator is calculated using the following example:

With a 5V supply, the output voltage swing is approximately $\pm 2.45V$ (load and supply voltage-dependent).

The gain of 4V/V allows an input swing of $\pm 0.6125V$.

Thus, the clipping current is $I_{MAX} = 0.6125V/R_{SHUNT}$.

See the differential amplifier curve of the Typical Characteristics, *Output Voltage vs Output Current*.

The over-range condition is internally detected as soon as the amplifier exceeds its linear operating range, not just a set voltage level. Therefore, the error or the over-range comparator level is reliably indicated in fault conditions such as output shorts, low load or low supply conditions. As soon as the output cannot drive the voltage higher, the flag is activated. This configuration is a safety improvement over a voltage level comparator.

NOTE: The internal resistance of the compensation coil may prevent high compensation current from flowing because of I_{COMP} driver overload. Therefore, the differential amplifier may not overload with this current. However, a fast rate of change of the primary current would be transmitted through transformer action and safely trigger the overload flag.

VOLTAGE REFERENCE

The precision 2.5V reference circuit offers low drift (typically 10ppm/K) and is used for internal biasing; it is also connected to the REF_{OUT} pin. The circuit is intended as the reference point of the output signal to allow a bipolar signal around it. This output is buffered for low impedance and tolerates sink and source currents of $\pm 5mA$. Capacitive loads can be directly connected, but generate ringing on fast load transients. A small series resistor of a few ohms improves the response, especially for a capacitive load in the range of 1 μ F. Figure 6 shows the transient load regulation with 1nF direct load.

The reference source is part of the integrated circuit and referenced to GND2. Large current pulses driving the compensation coil can generate a voltage drop in the GND connection that would add on to the reference voltage. Therefore, a low impedance GND layout is critical to handle the currents and the high bandwidth of this IC.

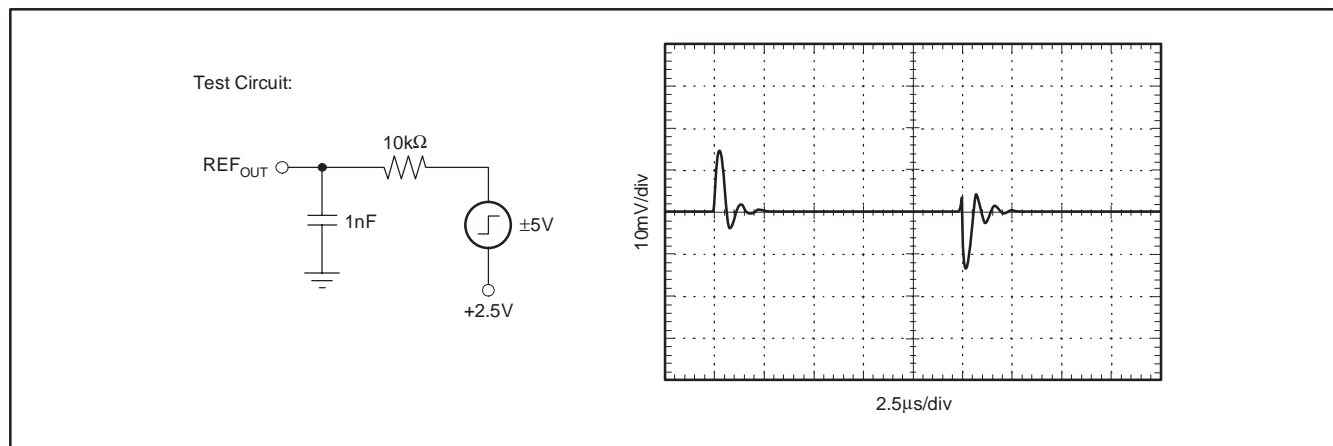

Figure 6. Pulse Response Test Circuit and Scope Shot of Reference

DEMAGNETIZATION

Iron cores are not immune to residual (remanence) magnetism. The residual remanence can produce a signal offset error, especially after strong current overload, which goes along with high magnetic field density. Therefore, the DRV401 includes a signal generator for a demagnetization cycle. The digital control pin, DEMAG, starts this cycle on demand after this pin is held high for at least 25.6 μ s. Shorter pulses are ignored. The cycle lasts for approximately 110ms. During this time, the Error flag is asserted low to indicate that the output is not valid. When DEMAG is high during power-on, a demagnetization cycle immediately initiates (12 μ s) after power-on ($V_{DD} > 4V$). Holding DEMAG low avoids this cycle at power-up (see the *Power-On and Brownout* section).

The probe circuit is in normal operation and oscillates during the demagnetization cycle. The outputs \overline{PWM} and PWM are active accordingly.

A demagnetization cycle can be aborted by pulling DEMAG low, filtered by 25 μ s to ignore glitches (see Figure 7). In a typical circuit, the DEMAG pin may be connected to the positive supply, which enables a degauss cycle every time the unit is powered on.

The degauss cycle is based on an internal clock and counter logic. The maximum current is limited by the resistance of the connected coil in series with the shunt resistor. The DEMAG logic input requires a +5V CMOS-compatible signal.

POWER-ON AND BROWNOUT

Power-on is detected with the supply voltage going higher than 4V at V_{DD1} . When DEMAG is high, a degauss cycle is started (see Figure 7a). During this time the ERROR flag remains low, indicating the not ready condition. Maintaining DEMAG low prevents this cycle, and the DRV401 starts operation approximately 32 μ s after

power-up. If no probe error conditions are detected within four full cycles (that is, the probe half-periods are shorter than 32 μ s and longer than 280ns), the compensation driver starts and the ERROR pin indicates the ready condition by going high, typically about 42 μ s after power-up.

NOTE: an external pull-up resistor is required to pull the ERROR pin high.

Both supply pins (V_{DD1} and V_{DD2}) should not differ by more than 100mV for proper device operation. They are normally connected together or separately filtered (see *Layout Considerations*).

The DRV401 tests for low supply voltage with a brown-out voltage level of +4V; proper power conditions must be supplied. Good power-supply and low ESR bypass capacitors are required to maintain the supply voltage during the large current pulses that the DRV401 can drive.

A critical voltage level is derived from the proper operation of the probe driver. The probe interface relies on a peak current flowing through the probe to trip the comparator. The probe resistance plus the internal resistance of the driver (see Electrical Characteristics specification, *Probe Coil Loop, Internal Resistor*) sets the lower limit for the acceptable supply voltage. Voltage drops lasting less than 31 μ s are ignored. The probe error detection activates the ERROR pin as soon as proper oscillation fails for more than 32 μ s.

A low supply voltage condition, or brown-out, is detected at +4V. Short and light voltage drops of less than 100 μ s are ignored, provided the probe circuit continues to operate. If the probe no longer operates, the ERROR pin goes active. Signal overload recovery is only provided if the probe loop was not discontinued.

A supply drop lasting longer than 100 μ s generates power-on reset. A voltage dip down to +1.8V (for V_{DD1}) also initiates a power-on reset.

a) Demagnetization cycle on power-up. With power-up, the V_{OUT} across the compensation coil centers around half the supply and then starts the cycle after the 4V threshold is exceeded. The ERROR flag resets to H after the cycle is completed.

b) Power-up without demagnetization. The probe oscillation $V(IS1)$ starts just before ERROR resets—15μs after the supply voltage crosses the 4V threshold.

c) Demagnetization cycle on command.

d) Abort of demagnetization cycle. The ERROR flag resets to H (as shown) and the output settles back to normal operation.

Figure 7. Demagnetization and Power-On Timing

ERROR CONDITIONS

In addition to the Over-Range flag that indicates signal clipping in the output amplifier (differential amplifier), a system error flag is provided. The ERROR flag indicates conditions when the output voltage does not represent the primary current. It is active during a demagnetization cycle, during a power-fail or brown-out. It also goes active with an open or short-circuit in the probe loop. As soon as the error condition is no longer present and the circuit has returned to normal operation, the flag resets.

Both the ERROR and Over-Range flags are open-drain logic outputs. They can be connected together for a wired-OR and require an external pull-up resistor for proper operation.

The following conditions result in ERROR flag activation (ERROR asserts low):

1. The probe comparator stays low for more than 32 μ s. This condition occurs either if the probe coil connection is open or if the supply voltage dips to the level where the required saturation current cannot be reached. During the 32 μ s timeout, the I_{COMP} driver remains active but goes inactive thereafter. In case of recovery, ERROR is low and the I_{COMP} driver remains in reset for another 3.3ms.
2. The probe driver pulse-width is less than 280ns for three consecutive periods. This condition indicates either a shorted field probe coil or a fully-saturated sensor at start-up. If this condition persists longer than 25 μ s and then recovers, the ERROR flag remains low and I_{COMP} is in reset for another 3.3ms. If the condition lasts less than 25 μ s, the ERROR flag recovers immediately and the I_{COMP} driver is not interrupted.
3. During demagnetization, if the cycle is aborted early by pulling DEMAG low, the ERROR flag stays low for another 3.3ms (I_{COMP} is disabled during this time).

4. An open compensation coil is detected (longer than 100 μ s). Note: the probe driver, the PWM signal filter and the I_{COMP} driver continue to function in normal mode—only the ERROR flag is asserted in this case. This condition indicates that not enough current is flowing in the I_{COMP} driver output; this condition might be the result of a high-resistance compensation coil or the connection of an external driver. Detection of this condition can be disabled by setting the CCdiag pin low.
5. At power-on after V_{DD1} crosses the +4V threshold, the ERROR flag is low for approximately 42 μ s.
6. A supply voltage low (brown-out) condition lasts longer than 100 μ s. Recovery is the same as power-up, either with or without a demag cycle.

PROTECTION RECOMMENDATIONS

The inputs IA_{IN1} and IA_{IN2} require external protection to limit the voltage swing beyond 10V of the supply voltage. The driver outputs I_{COMP1} and I_{COMP2} can handle high current pulses protected by internal clamp circuits to the supply voltage. If repeated over-currents of large magnitudes are expected, connect external Schottky diodes to the supply rails. This external protection prevents current flowing into the die.

The probe connections IS1 and IS2 are protected with diode clamps to the supply rails. In normal applications, no external protection is required. The maximum current must be limited to ± 75 mA.

All other pins offer standard protection—see the Absolute Maximum Ratings table.

The connection example in Figure 8 illustrates the few external components required for optimal performance. Each component is described in the following list:

I_P is the primary current to be measured; K_1 and K_2 connect to the compensation coil. $S1$ and $S2$ connect to the magnetic field probe. The dots indicate the winding direction on the sensor main core.

R_1 and R_2 form the shunt resistor R_{SHUNT} . This resistance is split into two to allow for adjustments to the required R_{SHUNT} value. The accuracy and temperature stability of these resistors are part of the final system performance.

R_3 and R_4 , together with C_3 and C_4 , form a network that reduces the remaining probe oscillator ripple in the output signal. The component values depend on the sensor type and are tailored for best results. This network is not required for normal operation.

R_5 is the dummy shunt (R_D) resistor used to restore the symmetry of both differential amplifier inputs. $R_5 = 4 \times R_{SHUNT}$, but the accuracy is less important.

R_6 and R_7 are pull-up resistors connected to the logic outputs.

C_1 and C_2 are decoupling capacitors. Use low ESR-type capacitors connected close to the pins. Use low impedance printed circuit board (PCB) traces, either avoiding vias (plated-through holes) or using multiple vias. A combination of a large ($> 1\mu F$) and a small ($< 4.7nF$) capacitor are suggested. When selecting capacitors, make sure to consider the large pulse currents handled from the DRV401.

D_1 and D_2 are protection diodes for the differential amplifier input. They are only needed if the voltage drop at R_{SHUNT} exceeds 10V at the maximum possible peak current.

LAYOUT CONSIDERATIONS

The DRV401 operates with relatively large currents and fast current pulses, and offers wide-bandwidth performance. It is often exposed to large distortion energy from both the primary signal and the operating environment. Therefore, the wiring layout must provide shielding and low-impedance connections between critical points.

Use low ESR capacitors for power-supply decoupling. Use a combination of a small capacitor and a large capacitor of $1\mu F$ or larger. Use low-impedance tracks to connect the capacitors to the pins.

Both grounds should be connected to a local ground plane. Both supplies can be connected together; however, best results are achieved with separate decoupling (to the local GND plane) and ferrite beads in series with the main supply. The ferrite beads decouple the DRV401, reducing interaction with other circuits powered from the same supply voltage source.

The reference output is referred to GND2. A low-impedance, star-type connection is required to avoid the driver current and the probe current modulating the voltage drop on the ground track.

The connection wires of the difference amplifier to the shunt must be low resistance and of equal length. For best accuracy, avoid current in this connection. Consider using a *Kelvin Contact*-type connection. The required resistance value can be set using two resistors.

Wires and PCB traces for $S1$ and $S2$ should be very close or twisted. I_{COMP1} and I_{COMP2} should also be wired close together. To avoid capacitive coupling, run a ground shield between the $S1/S2$ and I_{COMP} wire pair or keep them distant from each other.

The compensation driver outputs (I_{COMP}) are low frequency only; however, the primary signal (with high-frequency content present) is coupled into the compensation winding, the shunt, and the difference amplifier. Therefore, careful layout is recommended.

The output of REF_{OUT} and V_{OUT} can drive some capacitive loads, but avoid large direct capacitive loads; these loads increase internal pulse currents. Given the wide bandwidth of the differential amplifier, isolate any large capacitive load with a small series resistor. A small capacitor in the pF range can improve the transient response on a high resistive load.

The exposed thermal pad on the bottom of the package must be soldered to GND because it is internally connected to the substrate, which must be connected to the most negative potential. It is also necessary to solder the exposed pad to the PCB to provide structural integrity and long-term reliability.

POWER DISSIPATION

Using the thermally-enhanced PowerPAD™ SO and QFN packages dramatically reduces the thermal impedance from junction to case. These packages are constructed using a down-set lead frame upon which the die is mounted, as shown in Figure 9a and Figure 9b. This arrangement results in the lead frame being exposed as a thermal pad on the underside of the package. Figure 9 shows the SO-20 package as an example. Because this thermal pad has direct thermal contact with the die, excellent thermal performance can be achieved by providing a good thermal path away from the thermal pad.

The two outputs I_{COMP1} and I_{COMP2} are linear outputs. Therefore, the power dissipation on each output is proportional to the current multiplied by the internal voltage drop on the active transistor. For I_{COMP1} and I_{COMP2} , this internal voltage drop is the voltage drop to V_{DD2} or GND, according to the current-conducting side of the output.

Output short-circuits are particularly critical for the driver because the full supply voltage can be seen across the conducting transistor, and the current is not limited by anything other than the current density limitation of the FET. Permanent damage to the device can occur.

The DRV401 does not include temperature protection or thermal shut-down.

THERMAL PAD

Packages with an exposed thermal pad are specifically designed to provide excellent power dissipation, but board layout greatly influences overall heat dissipation. Table 1 shows the thermal resistance (T_{JA}) for the two packages with the exposed thermal pad soldered to a normal PCB, as described in Technical Brief SLMA002, *PowerPAD Thermally-Enhanced Package*. See also EIA/JEDEC

Specifications JESD51-0 to 7, *QFN/SON PCB Attachment* (SLUA271), and *Quad Flatpack No-Lead Logic Packages* (SCBA017). These documents are available for download at www.ti.com.

Table 1. $\theta_{JA/JP}$ Estimations According To EIA/JED51-7

	QFN-20	SO-20
θ_{JP}	9	9
θ_{JA} Still Air	40	35
θ_{JA} with Forced Airflow (150lfm)	38	32

θ_{JA} = junction-to-ambient thermal resistance,

θ_{JP} = junction-to-pad thermal resistance,

lfm = linear foot per minute.

NOTE: All thermal models have an accuracy $\approx 20\%$.

Measuring the temperature as close as possible to the exposed thermal pad is recommended. The relatively low thermal impedance, θ_{JP} , of less than 10°C/W (with some additional $^{\circ}\text{C/W}$ to the temperature test point on the PCB) allows good estimation of the junction temperature in the application.

The thermal pad on the PCB should contain nine or more vias for the QFN package. The same applies for the SO package, where the solder pad on the PCB can be larger than the exposed pad (for example, $6.6\text{mm} \times 18\text{mm}$) as recommended in the application literature noted previously.

Component population, layout of traces, layers, and air flow strongly influence heat dissipation. Worst-case load conditions should be tested in the real environment to ensure proper thermal conditions. Minimize thermal stress for proper long-term operation with a junction temperature well below $+125^{\circ}\text{C}$.

⁽¹⁾ The marketing status values are defined as follows:

ACTIVE: Product device recommended for new designs.

LIFEBUY: TI has announced that the device will be discontinued, and a lifetime-buy period is in effect.

NRND: Not recommended for new designs. Device is in production to support existing customers, but TI does not recommend using this part in a new design.

PREVIEW: Device has been announced but is not in production. Samples may or may not be available.

OBSOLETE: TI has discontinued the production of the device.

⁽²⁾ Eco Plan - The planned eco-friendly classification: Pb-Free (RoHS), Pb-Free (RoHS Exempt), or Green (RoHS & no Sb/Br) - please check <http://www.ti.com/productcontent> for the latest availability information and additional product content details.

TBD: The Pb-Free/Green conversion plan has not been defined.

Pb-Free (RoHS): TI's terms "Lead-Free" or "Pb-Free" mean semiconductor products that are compatible with the current RoHS requirements for all 6 substances, including the requirement that lead not exceed 0.1% by weight in homogeneous materials. Where designed to be soldered at high temperatures, TI Pb-Free products are suitable for use in specified lead-free processes.

Pb-Free (RoHS Exempt): This component has a RoHS exemption for either 1) lead-based flip-chip solder bumps used between the die and package, or 2) lead-based die adhesive used between the die and leadframe. The component is otherwise considered Pb-Free (RoHS compatible) as defined above.

Green (RoHS & no Sb/Br): TI defines "Green" to mean Pb-Free (RoHS compatible), and free of Bromine (Br) and Antimony (Sb) based flame retardants (Br or Sb do not exceed 0.1% by weight in homogeneous material)

⁽³⁾ MSL, Peak Temp. -- The Moisture Sensitivity Level rating according to the JEDEC industry standard classifications, and peak solder temperature.
